Sustainable Growth Rate, Optimal Growth Rate, and Optimal Payout Ratio: A Joint Optimization Approach

Abstract

Based upon flexibility dividend hypothesis DeAngelo and DeAngelo (2006), Blua Fuller (2008), and Lee et al. (2011) have reexamined issues of dividend policy. However, they do not investigate the joint determination of growth rate and payout ratio. The main purposes of this paper are (1) to extend Higgins’ (1977, 1981, and 2008) sustainable growth by allowing new equity issue, and (2) to derive a dynamic model which jointly optimizes growth rate and payout ratio.

By allowing growth rate and number of shares outstanding simultaneously change over time, we optimize the firm value to obtain the optimal growth rate and the steady state growth rate in terms of a logistic equation. We show that the steady state growth rate can be used as the bench mark for mean reverting process of the optimal growth rate. Using comparative statics analysis, we analyze how the optimal growth rate can be affected by the time horizon, the degree of market perfection, the rate of return on equity, and the initial growth rate. In addition, we also investigate the relationship between stochastic growth rate and specification error of the mean and variance of dividend per share.

Sustainable Growth Rate, Optimal Growth Rate, and Optimal Payout Ratio: A Joint Optimization Approach

1. Introduction

The relationship between the optimal dividend policy and the growth rate have been analyzed at length by Gordon (1962), Lintner (1964), Lerner and Carleton (1966), Modigliani and Miller (1961), Miller and Modigliani (1966), and others. In addition, Higgins (1977, 1981, and 2008) derives a sustainable growth rate assuming that a firm can use retained earnings and issue new debt to finance the growth opportunity of the firm. These authors, though pioneering in their efforts, focus on conducting their analyses at the equilibrium point while the focus of our paper is on analyzing the time path that leads to the equilibrium.

A growing body of empirical literature focuses on the relationship between the optimal dividend payout policy and the growth rate. For example, Rozeff (1982) showed that the optimal dividend payout is related to the fraction of insider holdings, the growth of the firm, and the firm’s beta coefficient. Grullon et al. (2002), DeAngelo et al. (2006), and DeAngelo and DeAngelo (2006) suggest that increases in dividends convey information about changes in a firm’s life cycle from a higher growth phase to a lower growth phase. Fama and French (2001) find that firms tend to pay dividends when they
experience high profitability and low growth rates by using the free cash flow hypothesis. Benartzi et al. (1997) and Grullon et al. (2002) show that dividend changes are related to the change in the growth rate and the change in the rate of return on asset.

Based upon flexibility dividend hypothesis DeAngelo and DeAngelo (2006), Blua Fuller (2008), and Lee et al. (2011) have reexamined issues of dividend policy. However, they do not investigate the joint determination of growth rate and payout ratio. The main purposes of this paper are (1) to extend Higgins’ (1977, 1981, and 2008) sustainable growth by allowing new equity issue; and (2) to derive a dynamic model which jointly optimizes growth rate and payout ratio. The present study deviates from earlier studies in two major aspects – First, this study presents a fully dynamic model for determining the optimal growth rate and the optimal dividend policy under stochastic conditions. Second, the focus is on tracing the time optimal path of the relevant decision variables and exploring their inter-temporal dependencies. The entire analysis in this paper is carried out in the stochastic control theory framework. The focus of the paper is on the rigorous development of a model for maximizing the value of the firm revealing (1) the exact relationships between the dividend policy and the time rate of change in growth, the profit possibility function and their distribution parameters, (2) the effect of varying time horizons, stochastic initial conditions, and the degree of market
perfection in determining the optimal growth rate and the optimal dividend policy for the firm, and (3) the implications stochasticity, stationarity (in the wide and the strict sense),\(^1\) and nonstationarity have on the rate of return and growth rate for corporate dividend policy decision under uncertainty.

Section 2 develops certain essential elements necessary for the control theory model presented in the subsequent sections. The fundamental model expresses a firm’s risk-adjusted stock price, assuming that (1) the new assets of a firm can be financed by new debt, external equity, and internal equity through retained earnings, (2) the rate of return on equity is stochastic, and (3) the growth rate varies over time. Section 3 presents the simultaneous solution to the optimization of the growth rate and outside equity financing. The model is analyzed under the dynamic growth rate assumption, and the optimal time path of growth is traced. Section 4 derives the equation for the optimal payout ratio from the model developed in the earlier sections. Section 5 deals with the stochastic growth rate and the identification of specification error introduced in the results by its misspecification as deterministic. This is followed by a short note on the stochasticity of the initial conditions and the final conclusions of the paper.

\(^1\) Pease see Anderson (1994).
2. Sustainable Growth Rate with New Equity Allowed

The main purpose of this section is to generalize Higgins’ (1977) sustainable growth rate with new equity issue allowed. To explore the relationship between the payout policy and the growth rate, we allow that a firm can finance growth by new debt, external equity, and internal equity through retained earnings, and thus leave the growth unconstrained by retained earnings. Our model operate under the usual assumptions of rational investor behavior, zero transactions costs, and the absence of tax differentials between dividends and capital gains and between distributed and undistributed profits. We further assume that the rate of return on equity is nonstationarily distributed and the growth rate varies over time. The model to maximize price is developed under stochastic growth rate assumptions, but first a simplified case under a deterministic time variant growth rate is presented. Under this specification neither the growth rate nor the level of assets in any time interval are predetermined. Thus, the asset size at time $t$ is

$$A(t) = A(0)e^{\int_0^t g(s)\,ds},$$

(1)

where $A(0) = $ initial total asset,

$A(t) = $ total assets at time $t$,

$g(t) = $ time variant growth rate, and

$s = $ the proxy of time in the integration.
Assuming a constant leverage ratio exists for a firm, the earnings of this firm can also be defined as a stochastic variable that is the product of the rate of return on equity times the total equity.

\[
\bar{Y}(t) = R OA(t) A(0) e^{\int_0^t g(s)ds}
\]

\[
= \frac{\bar{r}'(t)}{1-L} A(0)(1-L) e^{\int_0^t g(s)ds}
\]

\[
= \bar{r}(t) A'(0) e^{\int_0^t g(s)ds},
\]

where \( \bar{Y}(t) \) = earnings of the leveraged firm at time \( t \),
\( R OA(t) \) = the rate of return on total asset for a leverage firm at time \( t \),
\( \bar{r}(t) = \frac{R OA(t)}{1-L} \) = the rate of return on total equity at time \( t \), normally distributed with mean \( \bar{r}(t) \) and variance \( \sigma^2(t) \),
\( A'(0) = (1-L) A(0) \) = the total equity at time 0, and
\( L \) = the debt to total assets ratio.

In the rest of this study, we use the firm’s earnings in terms of rate of return on equity and total equity.

In addition, we denote \( \dot{n}(t) = dn(t)/dt \), where \( n(t) \) is the number of shares of common stock outstanding at time \( t \). We allow that a firm can finance its new investment through retained earnings, external equity, and new debt when it faces a growth opportunity. We also assume a target leverage ratio for a firm by allowing that a
firm can issue a proportional debt only to meet its target leverage ratio; therefore, a firm can growth not only by issuing new debt, but also by retaining its earnings and issuing external equity. Then, we can define the change of investment as follows:

$$\frac{dA(t)}{dt} = \dot{A}(t) = g(t)A(0)e^{\int_0^t g(s)ds} = \tilde{Y}(t) - \tilde{D}(t) + \lambda \tilde{n}(t) p(t) + L\dot{A}(t), \tag{3}$$

where $\tilde{D}(t)$ = the total dollar dividend at time $t$,

$p(t)$ = price per share at time $t$,

$\lambda$ = degree of market perfections, $0 < \lambda \leq 1$,

$\lambda \tilde{n}(t) P(t)$ = the proceeds of new equity issued at time $t$, and

$L$ = the debt to total assets ratio.

Note that the value of $\lambda$ equal to one indicates that the new shares can be sold by the firm at current market prices.

Eq. (3) is a generalized equation which Higgins (1977, 1981, and 2008) uses to derive his sustainable growth rate. Higgins’ equation allows only internal source and external debt financing. In our model, Eq. (3) also allows external equity financing.

The model defined in the Eq. (3) is for the convenience purpose. If we want to compare our model with Higgin’s (1977) sustainable growth rate model, we need to modify Eq. (3) as follows:

$$\dot{A}(t)\left[1 - \bar{r}(t)\left(1 - \bar{d}(t)\right)\right] = \bar{r}(t) \cdot A(t)\left[1 - \bar{d}(t)\right] + \frac{\bar{\lambda} \tilde{n}(t) p(t)}{1 - L}, \tag{4}$$
where $\tilde{d}(t)$ is the payout ratio at time $t$.

From Eq. (4), we can obtain the generalized sustainable growth rate as follows:

$$g(t) = \frac{\dot{A}(t)}{A(t)} = \frac{\dot{r}(t)[1-d(t)]}{1-\dot{r}(t)[1-d(t)]} + \frac{\lambda \tilde{n}(t) p(t)}{E(t)}$$

(5)

where $E(t) = $ the total equity at time $t$.

Eq. (5) will be reduced Higgins’ (1977, 1981, and 2008) sustainable growth rate if $\dot{n}(t) = 0$. Therefore, our model shows that Higgins’ (1977) sustainable growth rate is underestimated because of the omission of the source of the growth related to new equity issue which is the second term of our model. In the following section, we will use joint optimization approach to determine optimal growth rate and the optimal payout ratio.

3. Joint Optimization of Growth Rate and Payout Ratio

From equations (2) and (3), we can obtain the dividends per share as

$$\tilde{d}(t) = \frac{\tilde{D}(t)}{n(t)} = \frac{\tilde{r}(t) - g(t)}{n(t)} A'(0) e^{\int_0^t g(s)ds} + \lambda \tilde{n}(t) p(t)$$

(6)

and the mean and variance of the dividends per share can be expressed as

$$E[\tilde{d}(t)] = \frac{(\tilde{r}(t) - g(t)) A'(0) e^{\int_0^t g(s)ds} + \lambda \tilde{n}(t) p(t)}{n(t)}$$

(7)

$$Var[\tilde{d}(t)] = \frac{A'(0)^2 \sigma^2(t) e^{2 \int_0^t g(s)ds}}{n^2(t)}$$
Also, we postulate a utility function of the following form\(^2\)

\[
U[\ddot{d}(t)] = -e^{-\alpha \ddot{d}(t)}, \text{ where } \alpha > 0.
\]  

(8)

From the certainty-equivalent principle and the moment-generating technique,\(^3\) the certainty-equivalent dividend stream can be written as

\[
\hat{d}(t) = \left( \frac{\bar{F}(t) - g(t) A'(0) \int g(s)ds + \lambda \hat{n}(t) p(t)}{n(t)} \right) - \frac{a' A'(0)^2 \sigma^2(t) e^{\int_0^T g(s)ds}}{n(t)^2},
\]

(9)

where \(\hat{d}(t)\) is the certainty equivalent value of \(\ddot{d}(t)\) and \(a' = a/2\).

Following Lintner (1964), we observe that the stock price should equal the present value of this certainty equivalent dividend stream discounted at the cost of capital, that is,

\[
p(0) = \int_0^T \hat{d}(t) e^{-kt} dt,
\]

(10)

where 

\(p(0)\) = the stock price at the present time,

\(k\) = the cost of capital, and

\(T\) = the planning horizon.

This is the fundamental model that will be employed in subsequent sections to derive the functional forms of \(n(t)\) and \(g(t)\) that simultaneously optimize \(p(0)\) and find the optimal

\(^2\) For a detailed analysis of the various utility functions see Pratt (1964). Exponential, hyperbolic, and quadratic forms have been variously used in the literature but the first two seem to have preference over the quadratic form because the latter has the undesirable property that it ultimately turns downwards.

\(^3\) See Simon (1956) and Theil (1957) for the certainty equivalence principle and Hogg and Craig (2004) for the moment generating technique.
growth rate and the optimal payout ratio of a firm.

4. Optimal Growth Rate

In this section, we maximize \( p(0) \) simultaneously with respect to the growth rate and the number of shares outstanding. To a large extent, the profit possibility function for a firm is exogenously affected by a variety of time variant factors such as factor and product market conditions, but as Lintner (1964) points out, it could be conceivably affected by its past and present policies, say, with regard to research and development.

The decision on the rate of investment in any time interval, however, is largely endogenous to the firm, \textit{ceteris paribus}. Substituting Eq. (9) into Eq. (10), we observe

\[
p(0) = \int_0^T \left[ \left( \bar{F}(t) - g(t) \right) A'(0) e^{\int_0^t g(t') ds} + \lambda \hat{n}(t) \right] \frac{p(t)}{n(t)} + a' A'(0)^2 \sigma^2(t) e^{2 \int_0^t g(t') ds} \right] e^{-kt} dt. \quad (11)
\]

To maximize Eq. (11), we observe that

\[
p(t) = \int_t^T \hat{d}(s) e^{-k(s-t)} ds = e^{kt} \int_t^T \hat{d}(s) e^{-ks} ds. \quad (12)
\]

From Eq. (12), we can formulate a differential equation as

\[
\frac{dp(t)}{dt} = \dot{p}(t) = kp(t) - \hat{d}(t). \quad (13)
\]

Substituting Eq. (9) into Eq. (13), we have a differential equation as

\[
\dot{p}(t) + \left[ \frac{\lambda \hat{n}(t)}{n(t)} - k \right] p(t) = -H(t), \quad (14)
\]
where

\[
H(t) = \frac{\left(\bar{r}(t) - g(t)\right) A'(0) e^{\int_t^T g(s) ds} - a' A'(0) \sigma^2(t) e^{\int_t^T g(s) ds}}{n(t)}.
\]  

(15)

Solving the differential Eq. (14), we have\(^4\)

\[
p(t) = \frac{e^{kt}}{n(t)^2} \int_t^T H(s) n(t)^{l} e^{-ks} ds.
\]  

(16)

Then, Eq. (17) can be obtained from equations (15) and (16) implying that the initial value of a stock can be expressed as the summation of present values of its earnings stream adjusted by the risk taken by the firm.

\[
p(0) = \frac{1}{n(0)^2} \int_0^T \left[ n(t)^{l-1} \left(\bar{r}(t) - g(t)\right) A'(0) e^{\int_0^t g(s) ds} - a' A'(0) \sigma^2(t) n(t)^{l-2} e^{\int_0^t g(s) ds} \right] e^{-kt} dt
\]  

(17)

We maximize the stock price per share at time 0, \(p(0)\), defined in Eq. (17) by allowing both growth rate \(g(t)\) and number of shares outstanding \(n(t)\) change over time. When the growth rate \(g(t)\) is determined, then the amount of new investment can also be obtained. Once the amount of new investment and new equity issue \(\hat{n}_t p(t)\) are determined, then we can calculate the amount of the new debt and retained earnings (or dividend payout) at the same time. Therefore, it implies that we can obtain

\(^4\) For the derivation of the partial differential equation, please refer to the Appendix A.
the optimal growth rate and the optimal payout ratio simultaneously by maximizing the stock price.\(^5\)

Following Euler-Lagrange condition (see Chiang, 1984), we take the first order conditions on Eq. (17) with respect to \( t \) for both \( n(t) \) and \( g(t) \), and set these two first order conditions equal to zero.\(^6\) Then we can obtain equations (18) and (19) respectively.

\[
n(t) = \frac{(\lambda - 2) a'(0) \sigma^2(t) e^{\int_a^t \ddot{g}(s) ds}}{(\lambda - 1) \left[ \bar{\sigma}(t) - g(t) \right]}, \quad \text{and} \quad (18)
\]

\[
n(t) = \frac{2a' \sigma^2(t) e^{\int_a^t \ddot{g}(s) ds}}{\bar{\sigma}(t) - g(t) - \dot{g}(t) \frac{g(t)}{g(t)}}. \quad (19)
\]

From equations (18) and (19), we have

\[
\lambda g(t)^2 - \lambda \bar{\sigma}(t) g(t) + (2 - \lambda) \dot{g}(t) = 0. \quad (20)
\]

Under the assumption \( \bar{\sigma}(t) = \bar{\sigma} \), Eq. (18) is a nonlinear differential equation in \( g(t) \), which is the logistic equation discovered by Verhulst (1845 and 1847). Therefore, the optimal growth rate \( g^*(t) \) from Eq. (20) is \(^7\)

---

5 For example, we assume that the amount of new investment is $1,000,000, new equity issue is $200,000, the target debt to total asset ratio is 30%, and net income is $2,000,000. Then we know the new debt issue is $1,000,000 x 30% = $300,000. Therefore, the retained earnings will be $1,000,000 - $200,000, - $300,000 = $500,000. In other words, the optimal payout ratio is ($2,000,000 - $500,000)/$2,000,000 = 75%.

6 Lee et al. (2011) use only Eq. (18) to derive the optimal amount of new equity issue and optimal payout ratio. For the detailed derivation of equations (18) and (19), please see Appendix B.

7 To the best of our knowledge, this is the first logistic equation derived in finance research. For the detailed derivation of Eq. (21), please see Appendix C.
\[ g^*(t) = \frac{\bar{r}}{1 - \left(1 - \frac{\bar{r}}{g_0}\right)e^{\lambda t/\lambda^2}} \]
\[ = \frac{g_0\bar{r}}{g_0 + (\bar{r} - g_0)e^{2\lambda t/\lambda^2}} \]

where \( g_0 \) is the initial growth rate.

Eq. (21) shows an optimal growth rate, \( g^*(t) \), exists when we maximize a firm’s stock price per share by jointly determining the growth rate and the payout ratio. Therefore, different from Higgins’ (1977) sustainable growth rate model, the payout ratio (or retention rate) does not affect the optimal growth rate.

5. Comparative Statics Analyses on Optimal Growth Rate

The optimal growth rate can be determined by (1) the time horizon \( (t) \), (2) the degree of market perfection or imperfection \( (\lambda) \), (3) the rate of return on equity \( (\bar{r}) \), and (4) the initial growth rate \( (g_0) \). In addition, the optimal growth rate is a logistic equation which has a special characteristic called the “mean-reverting process”. In the following subsections, we will numerically and graphically show how the mean-reverting process of the optimal growth rate works; furthermore, we provide the sensitivity analysis and the partial derivatives on the optimal growth rate with respect to the time horizon \( (t) \), the degree of market perfection \( (\lambda) \), the rate of return on equity \( (\bar{r}) \), and the initial growth rate \( (g_0) \). We will discuss how these factors affect the optimal growth rate.
respectively.

5.1 Case I: Time Horizon

Taking the derivative of the optimal growth rate with respect to the time, we can obtain Eq. (22).

\[
\dot{g}^*(t) = \frac{\partial g^*(t)}{\partial t} = \frac{\bar{r} \left( 1 - \frac{\bar{r}}{g_0} \right) \left( \bar{r} \lambda \right)}{\left( 1 - \left( 1 - \frac{\bar{r}}{g_0} \right) e^{\sigma \mu/(\lambda-2)} \right)^2},
\]

where \( g^*(t) = \frac{\bar{r}}{1 - \left( 1 - \frac{\bar{r}}{g_0} \right) e^{\sigma \mu/(\lambda-2)}}. \)

From Eq. (22), we can find that the optimal growth rate follows a mean-reverting process. If the initial growth rate, \( g_0 \), is greater than the rate of return on equity, \( \bar{r} \), the change of the optimal growth rate, \( \dot{g}^*(t) \), is negative. If the initial growth rate is lower than the rate of return on equity, the change of the optimal growth rate is positive. If the initial growth rate is equal to the rate of return on equity, the change of the optimal growth rate is zero; therefore, the optimal growth rate is approaching the rate of return on equity, \( \bar{r} \), over time. Table 1 and Figure 1 show the time path of the optimal growth rate from the initial conditions \( g_0 \) to its steady state value.

<Insert Table 1>

<Insert Figure 1>
The important implications of the results derived from Eq. (22) and partially graphed in Figure 1 are as follows:

(i) Under a finite time horizon, \( g^* (t) = \bar{r} \) and \( g^* (t) = 0 \) when \( g_0 = \bar{r} \).

(ii) When time horizon approaches infinity, the optimal growth rate approaches the steady state value of \( \bar{r} \).

(iii) The greater the degree of imperfection in the market, as indicated by a lower value of \( \lambda, \ 0 < \lambda < 1 \), the slower the speed with which the firm attains the steady state optimal growth rate. One feasible reason is that the firm can issue additional equity only at a price lower than the current market price indicated by the value of \( \lambda < 1 \).

5.2 Case II: Degree of Market Perfection

Taking the derivative of the optimal growth rate with respect to the degree of market perfection, \( \lambda \), we can obtain Eq. (23).

\[
\frac{\partial g^* (t)}{\partial \lambda} = \frac{\bar{r}}{g_0} - 1 \left( e^{\lambda \bar{r}_t / (\lambda - 2)} \right)^2 \frac{2 \bar{r}_t}{(\lambda - 2)^2} - \left( 1 - \frac{\bar{r}}{g_0} \right) e^{\lambda \bar{r}_t (\lambda - 2)} \right],
\]

where \( g^* (t) = \frac{\bar{r}}{1 - \left( 1 - \frac{\bar{r}}{g_0} \right) e^{\lambda \bar{r}_t (\lambda - 2)}} \).
We find that the sign of Eq. (23) depends on the sign of \( \frac{\bar{r}}{g_0} - 1 \). If the initial growth rate is less than the rate of return on equity, Eq. (23) is positive; therefore, the optimal payout ratio at time \( t \) tends to be closer to the rate of return on equity if the degree of market perfection increases. Comparing Figure 1.a and Figure 1.c to Figure 1.b and Figure 1.d, we can find when the degree of market perfection is 0.95, the optimal growth rate will converge to its target rate (rate of return on equity) after 20 years. When the degree of market perfection is 0.60, the optimal growth rate cannot converge to its target rate (rate of return on equity) even after 30 years. Figure 2 shows the optimal growth rates of different rates of return on equity and degrees of market perfection when the initial growth rate is 5% and the time is 3. We find that the more perfect the market is, the faster the optimal growth rate adjusts; thus, the mean-reverting process of the optimal growth rate is faster if the market is more perfect.

<Insert Figure 2>

5.3 Case III: Rate of Return on Equity

Taking the derivative of the optimal growth rate with respect to the rate of return on equity, \( \bar{r} \), we can obtain Eq. (24).
\[
\frac{\partial \hat{g}^*(t)}{\partial \bar{r}} = \frac{g_0 \left\{ g_0 \left(1 - e^{\lambda \gamma/(\lambda - 2)}\right) + \left(g_0 - \bar{r}\right) \frac{\lambda t}{(\lambda - 2)} e^{\lambda \gamma/(\lambda - 2)} \right\}}{g_0 + (\bar{r} - g_0) e^{\lambda \gamma/(\lambda - 2)}},
\]

(24)

where \( g^*(t) = \frac{g_0 \bar{r}}{g_0 - (\bar{r} - g_0) e^{\lambda \gamma/(\lambda - 2)}} \).

Because the degree of market perfection \( \lambda \) is between zero and one, \( \frac{\lambda t}{(\lambda - 2)} \) is negative, and \( e^{\lambda \gamma/(\lambda - 2)} \) is between zero and one. The sign of Eq. (24) is therefore positive when the initial growth rate is less than the rate return on equity. That is, in order to catch up to the higher target rate, a firm should increase its optimal growth rate.

We further provide a sensitivity analysis to investigate the relationship between the change in the optimal growth rate and the change in the rate of return on equity. Panel A and C of Table 1 and Figure 1.a and Figure 1.c present the mean-reverting processes of the optimal growth rate when the rate of return on equity is 40%. Panel B and Panel D of Table 1 and Figure 1.b and Figure 1.d present those when the rate of return on equity is 50%. We find that, holding the other factors constant, the optimal growth rate under a 50% rate of return on equity is higher than the optimal growth rate under a 40% rate of return on equity. Figure 2 shows that, under different degrees of market perfection, the optimal growth rates increase when the rate of return on equity increases; therefore, when the rate of return on equity increases, the optimal growth rates increase under different conditions of initial growth rates, time horizons, and degrees of market perfection.
perfections.

5.4 Case IV: Initial Growth Rate

Taking the derivative of the optimal growth rate with respect to the initial growth rate, \( g_0 \), we can obtain Eq. (25).

\[
\frac{\partial g^* (t)}{\partial g_0} = \frac{\left( \frac{\bar{r}}{g_0} \right)^2 e^{\lambda \eta/(\lambda - 2)}}{1 - \left( 1 - \frac{\bar{r}}{g_0} \right) e^{\lambda \eta/(\lambda - 2)}}^2, \quad (25)
\]

where \( g^* (t) = \frac{\bar{r}}{1 - \left( 1 - \frac{\bar{r}}{g_0} \right) e^{\lambda \eta/(\lambda - 2)}} \).

We can easily determine that the sign of Eq. (25) is positive. From Table 1, we can also find the higher optimal growth rate if the initial growth rate is higher. Figure 1 shows that the line of the optimal growth rate over time does not cross over each other, meaning that the mean-reverting process of the optimal growth rate under an initial growth rate far from the objective value cannot be faster than that under an initial growth rate closer to the objective value.

From Eq. (21), we know that the optimal growth rate is not affected by payout ratio. It is only affected by the time horizon \( t \), the degree of market perfection or imperfection \( \lambda \), the rate of return on equity \( \bar{r} \), and the initial growth rate \( g_0 \).

This might imply that the sustainable growth rate instead of optimal growth rate is
affected by payout ratio. In the following section, we will develop the optimal dividend payout policy in terms of optimal growth rate.

6. Optimal Dividend Policy

In this section, we address the problem of an optimum dividend policy for the firm. Using the model developed in the earlier sections, we maximize $p(0)$ simultaneously with respect to the growth rate and the number of shares outstanding. We can derive a general form for the optimal payout ratio as follows:

$$\frac{D(t)}{Y(t)} = \left[ 1 - \frac{g^*(t)}{\bar{F}(t)} \right]^*,$$

$$1 + \left[ e^{kt - \lambda \int_0^t g^*(s) ds} \right] \lambda \left[ \frac{2 - \lambda}{\sigma^2(t)} \left( \frac{\bar{F} - g^*(t)}{\bar{F} - g^*(s)} \right) W \right],$$

where $W = \int_t^\tau e^{-\lambda \int_0^t g^*(u) du - \lambda s} \sigma^2(s)^{\lambda - 1} \left( \frac{\bar{F} - g^*(s)}{\bar{F} - g^*(s)} \right)^{2-\lambda} ds$.

Eq. (26) implies that the optimal payout ratio of a firm is a function of the optimal growth rate $g^*(t)$, the change in optimal growth rate $\dot{g}^*(t)$, the rate of return on equity $\bar{F}$, the degree of market perfection $\lambda$, the cost of capital $k$, the risk of the rate of return on equity $\sigma^2(t)$, and the change in the risk of rate of the return on equity $\dot{\sigma}^2(t)$. Previous empirical studies find that a firm’s dividend policy is related to the firm’s risk, growth rate, and proxies of profitability, such as the rate of return on assets and the change rate on assets.

---

8 For the detailed derivation of Eq. (26), please see the Appendix D.
market-to-book ratio (e.g., Benartzi et al., 1997; DeAngelo et al., 2006; Denis and Osobov, 2008; Fama and French, 2001; Grullon et al., 2002; and Rozeff, 1982). These studies, however, omit some important factors such as the degree of market perfection, the cost of capital, the rate of return on equity, the change in the growth rate, and the change in risk; therefore, our theoretical model implies that previous researchers might have used misspecified models to conduct their empirical research.

7. **Stochastic Growth Rate**

In this section we will discuss how the stochastic growth affect the specification error associated with expected dividend which has been defined in Eq. (7). We also discuss the implication of stochastic initial growth rate on the optimal growth rate.

7.1 **Stochastic Growth Rate and Specification Error**

We here attempt to identify the possible error in the optimal dividend policy introduced by misspecification of the growth rate as deterministic. Lintner (1964) explicitly introduced uncertainty of growth in his valuation model. The uncertainty is shown to have two components – one derived from the uncertainty of the rate of return and, second, from the increase in this uncertainty as a linear function of futurity. In the present analysis we introduced a fully dynamic time variant growth rate to clearly see the impact
of its stochasticity on the optimal dividend policy.

With the stochastic rate of return on equity, \( \bar{r}(t) \sim N(\bar{r}(t), \sigma^2(t)) \), the asset size and the growth rate for any time interval also become stochastic. This can be seen more clearly by rewriting Eq. (3) explicitly in the growth form as follows:

\[
\tilde{g}(t) = \frac{\dot{A}(t)}{A(t)} = b\bar{r}(t) + \frac{\lambda \dot{n}(t) p(t)}{(1-L)A(t)},
\]

(27)

where \( b \) is the retention rate and \( (1-L)A(t) \) is the total equity at time \( t \). Therefore, the growth rate of a firm is related not only to how much earnings it retains, but also to how many new shares it issues.

Thus, with a stochastic rate of return, the growth rate in Eq. (27) also becomes stochastic, \( \tilde{g}(t) \sim N(g(t), \sigma^2_\tilde{g}(t)) \). A further element of stochasticity in \( \tilde{g}(t) \) is introduced by the stochastic nature of \( \lambda \) indicating the uncertainty about the price at which new equity can be issued relative to \( p(t) \). Misspecification of the growth rate as deterministic in the earlier sections introduced an error in the optimal dividend policy, which we now proceed to identify.Reviewing equations (1) to (4) under a stochastic growth rate specification, we derive from Eq. (4) the expression Eq. (31) as follows:

\[
\tilde{d}(t) = \frac{\tilde{D}(t)}{n(t)} = \left[ \bar{r}(t) - \tilde{g}(t) \right] A'(o) e^{\int_o^t \tilde{g}(s) \, ds} + \lambda \dot{n}(t) p(t)
\]

(28)

It may be interesting to compare this model with the internal growth models.
Notice that if the external equity financing is not permissible, the growth rate, Eq. (27), is equal to the retention rate times the profitability rate, as in Lintner (1964) and Gordon (1963). Also, notice that under the no external equity financing assumption, Eq. (28) reduces to \( \tilde{d}(t) = \tilde{d}_o \exp\left( \int_{0}^{t} g(s) \, ds \right) \), which is Lintner’s Eq. (8) with the only difference that, in our case, the growth rate is an explicit function of time.

To carry the analysis further under a time variant stochastic growth rate, we derive the mean and variance of \( \tilde{d}(t) \) as follows:

\[
E[\tilde{d}(t)] = \frac{- \left( \bar{r}(t) - g(t) \right) A'(0) \exp\left( \int_{0}^{t} \tilde{g}(s) \, ds \right) + \lambda \tilde{n}(t) p(t) }{n(t)} \tag{29a}
\]

\[
\text{Cov}\left( \tilde{r}(t), A'(0) \exp\left( \int_{0}^{t} \tilde{g}(s) \, ds \right) \right) + E\left[ \tilde{\epsilon}(t) \exp\left( \int_{0}^{t} \tilde{g}(s) \, ds \right) \right]
\]

and

\[
\text{Var}\left[ \tilde{d}(t) \right] = \frac{A'(0)^2 \sigma^2(t) \exp\left( \int_{0}^{t} \tilde{g}(s) \, ds \right) + A'(0)^2 \text{Var}\left[ \tilde{\epsilon}(t) \exp\left( \int_{0}^{t} \tilde{g}(s) \, ds \right) \right]}{n(t)} + \frac{A'(0)^2 \text{Var}\left[ \tilde{\epsilon}(t) \exp\left( \int_{0}^{t} \tilde{g}(s) \, ds \right) \right]}{n(t)^2}, \tag{29b}
\]

where \( \tilde{\epsilon}(t) = \tilde{g}(t) - g(t) \).

Comparing Eq. (29) and Eq. (7), we observe that both the mean and the variance of \( \tilde{d}(t) \) will be subject to specification error if the deterministic growth rate is inappropriately employed. Eq. (29a) implies that the numerator in the equation for the
optimal payout ratio has the following additional element:

\[
-\text{Cov}\left(\hat{r}(t), A(o)e^{\int_0^t \hat{g}(s)ds}\right) + E\left(\hat{\epsilon}(t)e^{\int_0^t \hat{g}(s)ds}\right)
\]

\[
\frac{n(t)}{\text{Cov}\left(\hat{r}(t), A(o)e^{\int_0^t \hat{g}(s)ds}\right) + E\left(\hat{\epsilon}(t)e^{\int_0^t \hat{g}(s)ds}\right)}.
\] (30)

Now notice that the second term in the expression of Eq. (30) tends to be dominated more and more by the first term as the time \( t \) approaches to infinity.\(^9\)

Thus, the direction of error introduced in the optimal payout ratio when the growth rate is arbitrarily assumed to be non-stochastic increasingly depends upon the size of the covariance term in Eq. (30). If the covariance between the rate of return on equity and the growth rate is positive, the optimal payout ratio under the stochastic growth rate assumption would be lower even if the rate of return for the firm increases over time. In other words, the payout ratio in section 4 under the deterministic growth rate assumption is an over-estimate of the optimal payout ratio. On the other hand, if the covariance between the rate of return on equity and the growth rate is negative (that is, the higher the

\(^9\) From Astrom (2006), we also know that

\[
\text{plim}_{s \to \infty} \left[ \hat{\epsilon}(s)e^{\int_0^s \hat{g}(t)dt} \right] = \text{plim}_{s \to \infty} \left[ \hat{\epsilon}(s) \text{plim}_{s \to \infty} e^{\int_0^s \hat{g}(t)dt} \right], \quad (A)
\]

\[
\text{plim}_{s \to \infty} e^{\int_0^s \hat{g}(t)dt} = e^{\int_0^s \hat{g}(t)dt} . \quad (B)
\]

Substituting (B) into (A), we have

\[
\text{plim}_{s \to \infty} \left[ \hat{\epsilon}(s)e^{\int_0^s \hat{g}(t)dt} \right] = e^{\int_0^s \hat{g}(t)dt} \text{plim}_{s \to \infty} \left[ \hat{\epsilon}(s) \right] = 0 .
\]
growth rate, the lower the rate of return on equity), the payout ratio derived in the preceding section is an under-estimate of the optimal payout ratio.

7.2 Stochastic Initial Conditions

At this point a note on the stochasticity of the initial conditions and the significance of the time path of the growth rate is also in order. From the specification of the stochastic growth rate in the previous sub-section, it can be argued that the initial growth rate \( g_o \) in Eq. (21) and illustrated in Figure 1 is chosen by the management taking into account the uncertainty of the time path of return and its distribution parameters \( (\bar{r}(t), \sigma^2(t)) \).

Therefore, the determination of the initial growth rate is also stochastic, implying that \( g_o = \bar{r} \) can happen only in the expectation sense. Since \( g_o = \bar{r} \) is only one point from the entire distribution, there is only a small probability that the steady value of the optimal growth rate happens and that the optimal growth rate does not change over time. This further brings out the importance of analyzing the time path of the growth rate as it approaches the steady state value from the initial stochastic conditions. We feel that significant progress in financial decision making based on the detailed analysis of equilibrium values of the underlying parameters has been made in the literature, thanks to the pioneering efforts by Modigliani and Miller (1961), Gordon (1962), and Lintner (1964), to name only a few. Further research, however, needs to be done in tracing the
time path leading to these steady state values of parameters under uncertainty.

8. **Summary and Conclusion Remarks**

Our concern in this paper has been to sharpen the focus on corporate decisions concerning the optimal growth and dividend payout policies. The interdependence of corporate decisions on these two important policy variables is explicitly recognized in deriving the simultaneous solution to the problem of maximizing the present value of the firm. In more detail, we examine the time path of the optimal growth rate, starting from the stochastic initial conditions, and approaching its steady state value. Important insights into the effects of the degree of market perfection, rate of return on equity, and initial growth rate on the optimal growth rate are also developed. Furthermore, we derive the optimal payout policy under most general conditions with regard to the market imperfection, nonstationarity, and the stochasticity of the growth rate and the profitability rate. In particular, the error introduced in the optimal payout ratio by misspecification of the growth rate as deterministic is identified and shown to relate to its initial stochastic conditions. Finally, the model developed in this paper brings out explicitly the influence of riskiness of a non-stationary profitability rate on the optimal dividend policy. Important work, as mentioned earlier, in determining the optimal equilibrium values of corporate decision variables has been done by Gordon (1962), Lintner (1964), Modigliani
and Miller (1961), Miller and Modigliani (1966), DeAngelo et al. (1996), Fama and French (2001), DeAngelo and DeAngelo (2006), and Lee et al. (2011). The need, however, for further research in tracing the optimal time path under uncertainty leading to these equilibrium values and the relevant stability conditions remains, and the present paper is a modest step forward in that direction.
Appendix A. Derivation of Equation (16)

This appendix presents a detailed derivation of the solution to the variable partial differential equation, Eq. (14), which is similar to Gould’s (1968) Eq. (9) in investigating the adjustment cost. Following Gould’s (1968) approach, we first derive a general solution for a standard variable partial differential equation. Then we apply this general equation to solve Eq. (14). The standard variable partial differential equation can be defined as:

\[ \dot{p}(t) + g(t)p(t) = q(t) \]  \hspace{1cm} (A.1)

As a particular case of Eq. (A.1), the equation

\[ \dot{p}(t) + g(t)p(t) = 0 \quad \text{or} \quad \frac{\dot{p}(t)}{p(t)} = -g(t) \]  \hspace{1cm} (A.2)

has a solution

\[ p(t) = c \cdot \exp\left(-\int g(t) dt\right). \]  \hspace{1cm} (A.3)

By substituting constant \( c \) with function \( c(t) \), we have the potential solution to Eq. (A.1)

\[ p(t) = c(t) \cdot \exp\left(-\int g(t) dt\right). \]  \hspace{1cm} (A.4)

Taking a differential with respect to \( t \), we obtain:
\[ \dot{p}(t) = \dot{c}(t) \cdot \exp\left(-\int g(t) dt\right) - c(t) \cdot \exp\left(-\int g(t) dt\right) g(t) \]

\[ = \dot{c}(t) \cdot \exp\left(-\int g(t) dt\right) - p(t) g(t) \] \tag{A.5}

Therefore,

\[ \dot{p}(t) + p(t) g(t) = \dot{c}(t) \cdot \exp\left(-\int g(t) dt\right) . \] \tag{A.6}

From equations (A.1) and (A.6), we have

\[ \dot{c}(t) \cdot \exp\left(-\int g(t) dt\right) = q(t) . \] \tag{A.7}

Equivalently,

\[ \dot{c}(t) = q(t) \cdot \exp\left(\int g(t) dt\right) . \] \tag{A.8}

Therefore,

\[ c(t) = \int q(t) \cdot \exp\left(\int g(t) dt\right) dt . \] \tag{A.9}

Substituting Eq. (A.9) into Eq. (A.3), we have the general solution of Eq. (A.1),

\[ p(t) = \exp\left(-\int g(t) dt\right) \cdot \left[ \int q(t) \exp\left(\int g(t) dt\right) dt \right] . \] \tag{A.10}

To solve Eq. (12), we will apply the above result. Let \( g(t) = \lambda \frac{\dot{n}(t)}{n(t)} - k \) and \( q(t) = -H(t) . \)

Since

28
\[
\exp \left( \int g(t) dt \right) = \exp \left( \int \left( \frac{\dot{n}(t)}{n(t)} - k \right) dt \right)
\]
\[
= \exp \left( \frac{\dot{n}(t)}{n(t)} dt - kt \right)
\]
\[
= \exp \left( \frac{\lambda}{n(t)} \ln(n(t)) - kt + c \right)
\]
\[
= c_1 \cdot n(t)^{\lambda} \exp(-kt),
\]
where \( c_1 > 0 \).

Then we have,
\[
P(t) = c_2 \cdot n(t)^{-\lambda} \exp(kt) \cdot \left[ \int q(t) c_3 \cdot n(t)^{\lambda} \exp(-kt) dt \right],
\]
where \( c_2 > 0 \), and \( c_3 > 0 \)

or equivalently,
\[
P(t) = c_4 \cdot \frac{\exp(kt)}{n(t)^{\lambda}} \cdot \left[ \int -H(t) \frac{n(t)^{\lambda}}{e^{kt}} dt \right],
\]
where \( c_4 > 0 \).

Finally, we have
\[
P(t) = c \frac{\exp(kt)}{n(t)^{\lambda}} \cdot \int H(t) n(t)^{\lambda} e^{-kt} dt,
\]
(A.14)

Changing from an indefinite integral to a definite integral, Eq. (A.13) can be shown as
\[
p(t) = \frac{\exp(kt)}{n(t)^{\lambda}} \int_{t}^{T} H(s) n(s)^{\lambda} e^{-ks} ds,
\]
which is Eq. (16).
APPENDIX B. Derivation of Equation (20)

This appendix presents a detailed procedure for deriving Eq. (20). Following Euler-Lagrange condition (see Chiang, 1984), we first take the first order condition on Eq. (17) with respect to $t$ allowing only $n(t)$ and $g(t)$ to change over time, and set the first order condition equal to zero. Then we obtain

$$\frac{\partial p(0)}{\partial t} = (\lambda - 1)n(t)^{\lambda - 2} \dot{n}(t)[r(t) - g(t)] A'(0) \exp\left(\int_0^t g(s) ds\right)$$

$$-a'A^2(0)\sigma^2(t)(\lambda - 2)n(t)^{\lambda - 3} \dot{n}(t) \exp\left(2\int_0^t g(s) ds\right) = 0 \quad (B.1)$$

$$\frac{\partial p(0)}{\partial t} = [n(t)^{\lambda - 1} r(t) A'(0) g(t) \exp\left(\int_0^t g(s) ds\right)]$$

$$-n(t)^{\lambda - 1} A'(0) g(t) \exp\left(\int_0^t g(s) ds\right)$$

$$-n(t)^{\lambda - 1} A'(0) g(t)^2 \exp\left(\int_0^t g(s) ds\right)$$

$$-\left[2a'A^2(0)\sigma^2(t)n(t)^{\lambda - 2} g(t) \exp\left(2\int_0^t g(s) ds\right)\right] = 0 \quad (B.2)$$

After rearranging equations (B.1) and (B.2), we can obtain equations (18) and (19).

$$n(t) = \frac{(\lambda - 2)a'A'(0)\sigma^2(t) \exp\left(\int_0^t g(s) ds\right)}{(\lambda - 1)[r(t) - g(t)]} \quad (16)$$

$$n(t) = \frac{2a'A'(0)\sigma^2(t) \exp\left(\int_0^t g(s) ds\right)}{r(t) - g(t) \frac{\dot{g}(t)}{g(t)}} \quad (17)$$

Therefore, from equations (18) and (19), we can derive the following well-known logistic differential equation as
\[ \lambda g(t)^2 - \lambda r(t) g(t) + (2 - \lambda) \dot{g}(t) = 0. \] (20)
APPENDIX C. Derivation of Equation (21)

This appendix presents a detailed derivation of the solution to the Eq. (21). To solve partial differential equation, Eq. (20), which is a logistic equation (or Verhulst model) first published by Pierre Verhulst (1845 and 1847). To solve the logistic equation, we first rewrite Eq. (20) as a standard form of logistic equation.

\[
\frac{dg(t)}{dt} = Ag(t) \left(1 - \frac{g(t)}{B}\right). \tag{C.1}
\]

where

\[
A = \frac{\lambda \bar{r}}{(2-\lambda)} \text{ and } B = \bar{r}.
\]

Using separation of variables to separate \(g\) and \(t\):

\[
Adt = \frac{dg(t)}{g(t)\left(1 - \frac{g(t)}{B}\right)} = \frac{dg(t)}{g(t)} + \frac{dg(t)}{B \left(1 - \frac{g(t)}{B}\right)} \tag{C.2}
\]

We next integrate both sides of Eq. (C.2),

\[
At + C = \ln(g(t)) - \ln\left(1 - \frac{g(t)}{B}\right). \tag{C.3}
\]

Taking the exponential on both sides of Eq. (C.3),

\[
C \cdot \exp(At) = \frac{g(t)}{1 - \frac{g(t)}{B}}. \tag{C.4}
\]
When \( t = 0 \), \( g(t) = g_0 \) and Eq. (C.4) can be written as

\[
C = \frac{g_0}{1 - \frac{g_0}{B}} - \frac{Bg_0}{B - g_0}. \tag{C.5}
\]

Substitute Eq. (C.5) into Eq. (C.4),

\[
\frac{Bg_0}{B - g_0} \cdot \exp(At) = \frac{g(t)}{1 - \frac{g(t)}{B}}. \tag{C.6}
\]

Solving for \( g(t) \),

\[
g(t) = \frac{Bg_0 \exp(At)}{B - g_0} \left[ 1 + \exp(At) \right] = \frac{Bg_0 \exp(At)}{B - g_0 + g_0 \exp(At)} = \frac{Bg_0}{g_0 + (B - g_0) \exp(-At)}. \tag{C.7}
\]

Substitute \( A = \frac{\lambda \varphi}{(2 - \lambda)} \) and \( B = \varphi \) into Eq. (C.7), we finally can get the solution of Eq. (20),

\[
g(t) = \frac{\varphi}{(1 - L)} \left[ 1 + \left( \frac{\varphi}{g_0} - 1 \right) \exp\left( \frac{\lambda \varphi t}{\lambda - 2} \right) \right],
\]

which is Eq. (21).
APPENDIX D. Derivation of Equation (26)

This appendix presents a detailed derivation of Eq. (26). To obtain the expression for optimal $n(t)$, given $\overline{r}(t) = \overline{r}$, we substitute Eq. (21) into Eq. (18) and obtain

$$n(t) = \frac{(2 - \lambda) a' A'(0) \sigma^2(t) \int_{0}^{\infty} g'(s) ds}{(1 - \lambda) \left( \overline{r} - g^*(t) \right)}.$$  \hspace{1cm} (D.1)

From equations (15), (18), and (21), we have

$$H(t) = \frac{\left( \overline{r} - g^*(t) \right)^2 (1 - \lambda)}{a' \sigma^2(t) (2 - \lambda)^2}.$$  \hspace{1cm} (D.2)

Substituting equations (D.1) and (D.2) into Eq. (16) we obtain

$$p(t) = \left[ \frac{e^{kt}}{n(t)^{1/\lambda}} \frac{1 - \lambda}{a' (2 - \lambda)^2} \int_{0}^{\infty} \frac{n(s)^{1/\lambda}}{\sigma^2(s) \left( \overline{r} - g^*(s) \right)^{1/\lambda}} e^{-ks} ds \right] W,$$

where $W = \int_{0}^{\infty} e^{kt} \frac{(2 - \lambda) \sigma^2(t) \int_{0}^{\infty} g'(s) ds}{(1 - \lambda) \left( \overline{r} - g^*(t) \right)^{1/\lambda}} ds$.  \hspace{1cm} (D.3)

From Eq. (D.1), we have

$$\dot{n}(t) = \frac{(2 - \lambda) a' A'(0) \sigma^2(t) \int_{0}^{\infty} g'(s) ds + (2 - \lambda) a' A(0) \sigma^2(t) g^*(t) \int_{0}^{\infty} g'(s) ds}{(1 - \lambda) \left( \overline{r} - g^*(t) \right)}.$$  \hspace{1cm} (D.4)

From equations (D.3) and (D.4), we have the amount generated from the new equity issue.
\[ \dot{n}(t)p(t) = \frac{A(0)}{\sigma^2(t)} \left( \sigma^2(t) + \sigma^2(t)g^*(t)(\bar{\sigma} - g^*(t)) + \sigma^2(t)\hat{g}^*(t) \right) \cdot \left[ e^{\lambda t} - \int_0^t g^*(s)ds \right] W \]

\[ \text{(D.5)} \]

From equations (1), (6), and (D.5), we can obtain \( \bar{D}(t) = n(t)\bar{d}(t) \) and

\[ \bar{Y}(t) = \frac{\bar{r}(t)A(0)e^{\int_0^t g^*(s)ds}}{\lambda(2 - \lambda)\sigma^2(t)(\bar{\sigma} - g^*(t))^{2-\lambda}}. \]

Therefore, the optimal payout ratio can be written as

\[ \frac{\bar{D}(t)}{\bar{Y}(t)} = \left[ 1 - \frac{g^*(t)}{\bar{r}(t)} \right] \cdot \left[ 1 + \left[ e^{\lambda t} - \int_0^t g^*(s)ds \right] \frac{\lambda \left( \sigma^2(t) + \sigma^2(t)g^*(t)(\bar{\sigma} - g^*(t)) + \sigma^2(t)\hat{g}^*(t) \right)}{(2 - \lambda)\sigma^2(t)(\bar{\sigma} - g^*(t))^{3-\lambda}} W \]

\[ \text{(26)} \]

where \( W = \int_t^{\bar{\tau}} e^{\lambda t} \sigma^2(s)^{\lambda-1} (\bar{\sigma} - g^*(s))^{2-\lambda} ds \).

Table 1. Mean-reverting process of the optimal growth rate

This table shows the mean-reverting process of the optimal growth rate for thirty years. Panel A presents the values of the optimal growth rate under different settings of the initial growth rate when the rate of return on equity is equal to 40% and the degree of market perfection is equal to 0.95. Panel B presents the values of the optimal growth rate when the rate of return on equity is equal to 40% and the degree of market perfection is equal to 0.60. Panel C presents the values of the optimal growth rate when the rate of return on equity is equal to 50% and the degree of market perfection is equal to 0.95. Panel D presents the values of the optimal growth rate when the rate of return on equity is equal to 50% and the degree of market perfection is equal to 0.60.

Figure 1. Sensitivity Analysis of the Optimal Growth Rate

The figures show the sensitivity analysis that how the time horizon \( t \), the degree of market perfection \( \lambda \), the rate of return on equity \( \hat{r}/1-L \), and the initial growth rate \( g_o \) affect the optimal growth rate. Figure 1.a presents the mean-reverting process assuming that the rate of return on equity is 40% and the degree of market perfection is 0.95. Each line shows the optimal growth rates over 30 years with different initial growth rates. Figure 1.b presents the mean-reverting process assuming that the rate of return on equity is 40% and the degree of market perfection is 0.60. Figure 1.c presents the mean-reverting process of the optimal growth rate assuming that the rate of return on equity is 50% and the degree of market perfection is 0.95. Figure 1.d presents the mean-reverting process of the optimal growth rate assuming that the rate of return on equity is 50% and the degree of market perfection is 0.60.

Figure 1.a  \( ROE = 40\%; \lambda = 0.95 \)

Figure 1.b  \( ROE = 40\%; \lambda = 0.60 \)

Figure 1.c  \( ROE = 50\%; \lambda = 0.95 \)

Figure 1.d  \( ROE = 50\%; \lambda = 0.60 \)
Figure 2. Optimal Growth Rate with respect to the Rate of Return on Equity and the Degree of Market Perfection

The figure shows the optimal growth rates using different rates of return on equity and degrees of market perfection when the initial growth rate is 5% and the time is 3. The rates of return on equity range from 5% to 50%. The degrees of market perfection range from 0.05 to 1.

\[ g_0 = 5\% \text{ and } t = 3 \]
